We present the case of a 44-year-old man, construction worker, hypertensive, smoker, with rheumatoid arthritis under prednisolone 10mg/day for 10 months. Gingival crevice disease. The patient was referred to the Emergency Department after 5 days of right chest pain with pleuritic features, cough, purulent sputum and dyspnea grade 3 mMRC, along with several weeks of indolent symptoms (anorexia, weight loss and night sweats). Polypneic with abdominal breathing and hypotensive. Initial blood tests showed an increase in inflammatory markers, hypoxemic respiratory failure and hyperlactacidemia. A thick walls cavitation, with an hydroaereal level was present in the chest X-ray (Fig 1). Thoracic computerized tomography (CT) shows a voluminous apparently loculated image occupying almost all of the right lung field associated with homolateral pleural effusion; a nodular image of about 28 mm with hydroaereal content located to the lower left lobe and at least two other identical smaller images in the same lobe (Fig 2). Diagnosed with lung abscess (LA), he was admitted to Intensive Care in septic shock under invasive ventilation and aminergic support, starting empirically piperacillin/tazobactam. The evaluation of pleural effusion (PE) reveals empyema fluid with an increased ADA of 158 IU/L. Tube thoracostomy with 3 chest tubes was performed. No structural changes in bronchofibroscopy (FB). PE culture identifies H. influenzae, S. parasanguinis and S. salivarius, allowing targeted therapy with clindamycin, fulfilling 35 days. Sterile blood cultures. PE cytology without malignancy. Tuberculosis excluded (PE and sputum with negative acid-fast bacilli (AFB) smear and culture; negative polymerase-chain-reaction assay for M. tuberculosis on bronchoalveolar lavage (BAL) and PE). Follow-up at 3 months with sterile BAL cultures and negative AFB BAL smear. CT improvement, with only residual changes, 6 months later.

LA consists of pulmonary parenchymal necrosis caused by microbial infection. Primary in 80% of cases. Inoculum aspiration from gingival crevice, poor dental hygiene are the main causes\(^1\). It as been noticed the close relationship with bacteria found in the oral cavity and gingival sulci. Steroids and smoking are important risk factors\(^2,3\). Cough, sputum, fever and systemic manifestations are a common presentation. Typically diagnosed with chest X-ray, anatomical definition is improved with CT. Despite difficult cultural isolation due to frequent contamination, Gram and sputum cultures are indicated as well as blood and PE cultures. FB is important in obtaining a cultural sample and exclusion of another etiology. Bacillary disease should be excluded. Anaerobes are present in 60-80% of cases, with frequently associated oral Streptococcus, 90% are polymicrobial\(^4\). Our patient’s agents were facultative oral anaerobes. Etiological agents and associated comorbidities are essential in defining therapeutic strategy\(^5,6\).

Antibiotics are usually maintained until radiological resolution or stable residual lesion, this may require several months and can be performed with an outpatient oral regimen. Bronchial obstruction, diameter >6cm, neoplasia, immunodepression and resistant microorganisms are predictors of poor therapeutic response\(^7,8\), 90-95% of primary abscesses can cure\(^9,10\). Mortality rate in the immunocompromised may exceed 75%\(^11\).

In summary, the authors, regarding an exuberant radiological presentation, intend to emphasize the relevance of microbiological isolation in targeting antimicrobial options, enabling faster outpatient treatment, avoiding prolonged hospitalization and complications inherent to it.
