Spontaneous pneumomediastinum

Neumomediastino espontáneo

Pneumomediastinum is defined as the presence of air in the mediastinal cavity. Can be classified into two categories: secondary pneumomediastinum, when there is a causative etiological factor and spontaneous pneumomediastinum, without a clear etiology. Spontaneous pneumomediastinum is a rare disease in adults and most often affects young adults males in a relation to females of 8:1. Is usually benign, self-limited and just recurred in rare cases. Sometimes the diagnosis on chest radiography can be difficult.

The authors describe a case of a young man, 19 years old, crew ambulances worker, occasional smoker (less than one packet per year), with no relevant medical history or usual medication that appealed to the emergency department with central chest pain with pleuritic characteristics associated with dyspnea that started on resting. The patient denied recent trauma, physical exertion or invasive medical examinations. The objective examination showed cervical subcutaneous emphysema without any other changes. Electrocardiogram and blood tests including hemogram, renal and hepatic parameters, C reactive protein, D-dimers and troponin were normal. Chest radiography and computed tomography showed cervical subcutaneous emphysema without any other changes.

The patient was admitted to the Pulmonary Department for 4 days where he had rest, oxygen therapy and symptomatic relief. The patient presented clinical improvement without presenting recurrence until the present time.
